Interpretation of Some Results of Radiotherapy and an Attempt at Determining a Logical Technique of Treatment[1]

De Quelques Resultats de la Radiotherapie et Essai de Fixation d'une Technique Rationnelle

J. BERGONIÉ AND L. TRIBONDEAU

Comptes-Rendus des Séances de l'Académie des Sciences 143, 983-985, 1906.
Translated by Gilbert Fletcher. Radiat Res. 1959

- The "Law of Bergonie and Tribondeau":
  - "X-rays are more effective on cells which have a greater reproductive activity; the effectiveness is greater on those cells which have a longer dividing future ahead, on those cells the morphology and the function of which are least fixed. From this law it is easy to understand that roentgen radiation destroys tumors without destroying healthy tissues."

The other thing Bergonie and Tribondeau said:

From the standpoint of the practice of radiotherapy, one must learn from these facts that one must avoid the production of atypical mitoses by radiotherapeutic treatments. It seems pretty clear that the practice of delivering small and repeated doses, in contradistinction to the technique of few and heavy doses, is more apt to produce these nondestructive irritations with resulting monster cells. **Therefore, one should prefer the method of massive doses.**

The ideal technique…would be to make this complex tissue absorb in one sitting the maximal dose of radiation compatible with the preservation of the other elements one wishes to preserve.

Dr. William D. Coolidge *and his NEW*

MAGIC RAY

Producing as Many ELECTRONS Every SECOND as a TON of RADIUM

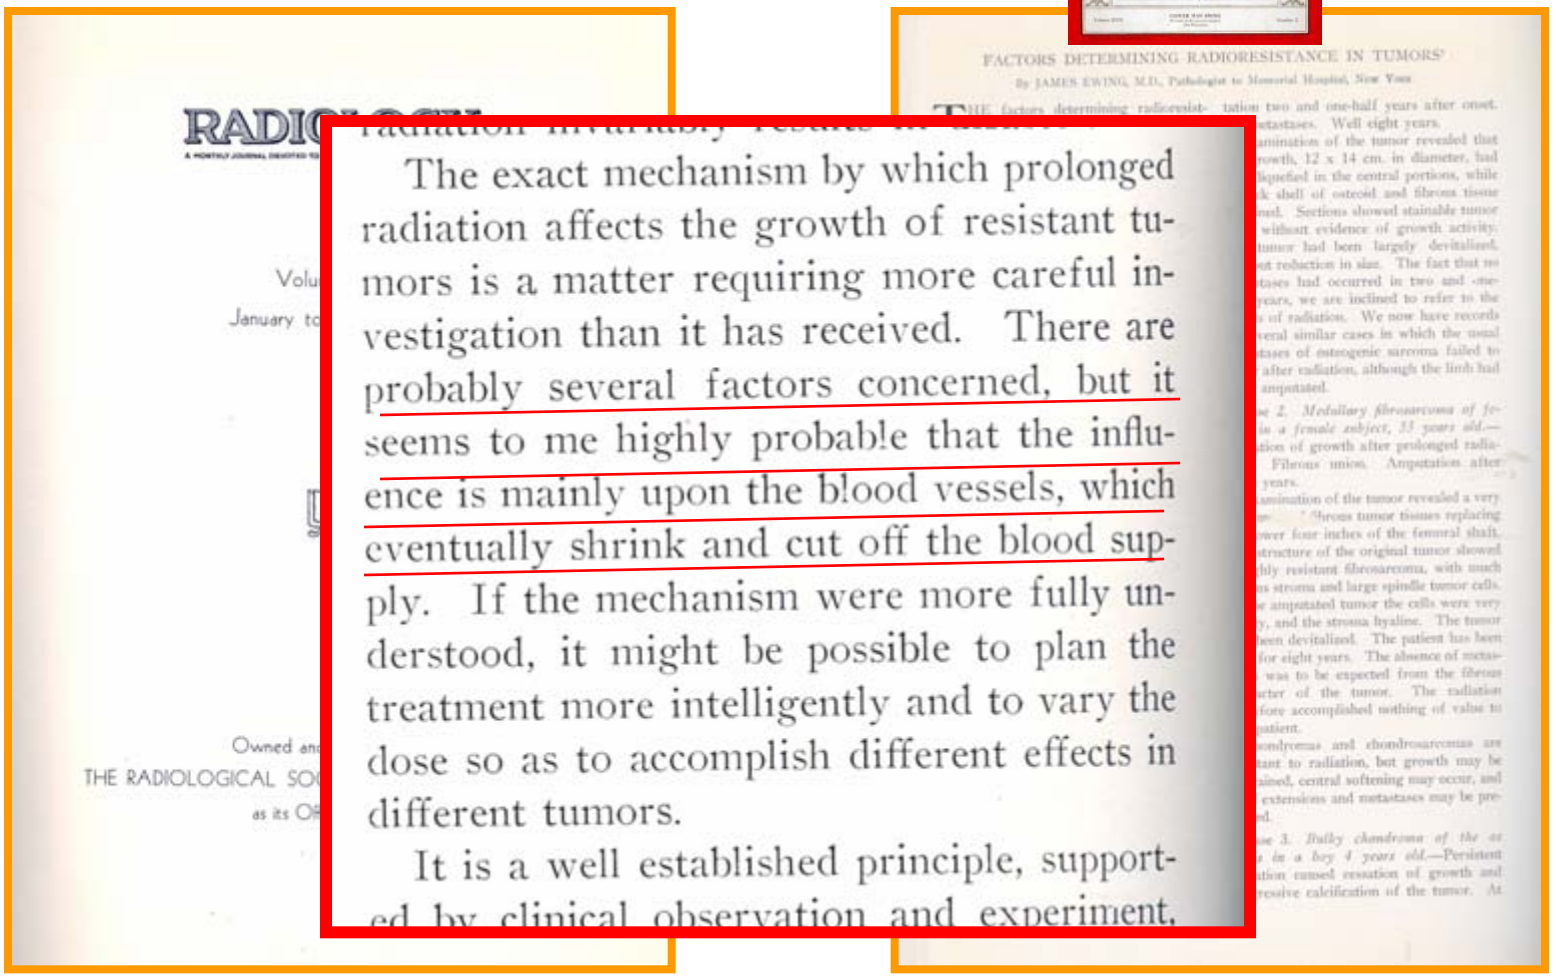
WHAT will it do for Humanity ?

By Robert Merrill

Dr. Coolidge, assistant director of the Research Laboratories of the General Electric Company, Schenectady, recently startled scientists by his cathode tube

In the picture is shown the new type of vacuum tube, perfected by Dr. Coolidge, which projects the magic cathode ray, the modern alchemist that changes solids into liquids and liquids into solids. [illegible] capabilities in the animal world have not been definitely determined, but it is known to produce marvelous changes in living tissues

Notable science, ca. 1930: James Ewing



The exact mechanism by which prolonged radiation affects the growth of resistant tumors is a matter requiring more careful investigation than it has received. There are probably several factors concerned, but it seems to me highly probable that the influence is mainly upon the blood vessels, which eventually shrink and cut off the blood supply. If the mechanism were more fully understood, it might be possible to plan the treatment more intelligently and to vary the dose so as to accomplish different effects in different tumors.

It is a well established principle, support-

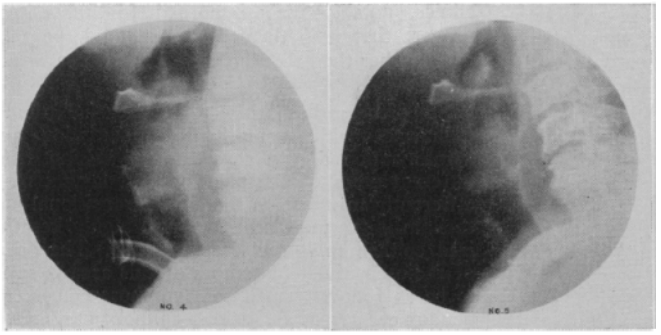
CARCINOMA OF THE LARYNX*

OBSERVATIONS ON CASES TREATED BY PROTRACTED (COUTARD) ROENTGEN THERAPY

By L. H. Garland, M. D.
San Francisco

Coutard believes it is always necessary to treat patients until a marked radio-epithelitis has developed. If the tumor has entirely disappeared by that time, and if its histological appearance suggests that it is of a very anaplastic type, treatment is discontinued. If, on the other hand, it is of a highly differentiated type, treatment may be continued; the duration of further treatment and the extent of further dosage depends upon personal judgment and experience.



Typical dose: 6000 r, 6d/wk, 200 kV
Alternate single fields, tumor+3cm
3600 to more affected side, 2400 to other

(With Eight Text-figures)

CONTENTS

1. INTRODUCTION

A considerable amount of experimental work has by now been done on the production of chromosome aberrations by radiation. The data are particularly extensive for the sperm cells of *Drosophila* and for the microspores of *Tradescantia*. There are certain important differences in the behaviour of these two materials, which seem to suggest that in the *Drosophila* sperm breaks produced by the radiation remain as such until fertilization (Muller, 1940), while in *Tradescantia* the combination of broken ends to form new arrangements, or to reform the old ones, takes place within periods of a few minutes to an hour after irradiation (Sax, 1940). In view of these differences it is probably best to treat each of the organisms separately. In this paper we consider only *Tradescantia*, and it should not be assumed that our conclusions apply to other organisms.

The experimental data on which we base our analysis is due to workers at Harvard University (Sax, Giles) and at Cambridge University (Thoday, Kotval, in conjunction with the present authors). Data are available both for microspores irradiated in the resting stage following meiosis, when the chromosomes are unsplit, and for microspores irradiated in the prophase of the first pollen-grain mitosis when the chromosomes are split. The deduction that in *Tradescantia* the chromosomes are already split 24 hr. before metaphase was made by Mather (1937). We consider this deduction certain for the following reason, among others. If the irradiation is made 24 hr. before metaphase the interchanges are mainly chromatid interchanges, and only a small minority are chromosome interchanges, showing that at the time of interchange few if any of the chromosomes are single. But we know that interchange occurs within a few minutes of irradiation (see § 2) because only on this basis can we explain a dependence, of the number of interchanges produced by a given dose, on the intensity at which the radiation is delivered.

In both cases the chromosomes are examined at the metaphase or anaphase of the pollen-grain mitosis. For a detailed description and photographs and diagrams of the

The 1942 Lea-Catcheside paper

- Concerned with the rate of chromatid interchanges as function of radiation dose
- The "D^2" comes from the expectation of kinetics similar to a bimolecular reaction
- Here, the two components are essentially the same entity, namely a broken chromatid

$$[A]+[B]\rightarrow[AB]$$

$$\frac{d[AB]}{dt}=k[A][B]$$

$$\frac{d[chromatid\_exchanges]}{dt}=k[chromatidbreaks]^2$$

$$\frac{d[chromatid\_exchanges]}{dt}=k'[dose]^2$$

The 1942 Lea-Catcheside paper, continued

- There was also a factor proposed to modify the "D^2" term with the term *G*
- The *α* term counts double strand breaks as a function of dose
- Purpose of *G* was to account for exposures that took enough time for there to be decay of the chromatid breaks produced as the radiation exposure continues

$$\alpha D + \beta D^2 G$$

$$G = (2/D^2) \int_{-\infty}^{\infty} \dot{D}(t)dt \int_{-\infty}^{t} e^{-\lambda(t-t')} \dot{D}(t')dt'$$

1940s, 1950s….and continuing on for a while: A resurrection of an old trick to give large doses—”grid” or “sieve” radiotherapy

RADIOTHERAPY OF ACCESSIBLE MALIGNANT TUMOURS BY ALTERNATING CHESS-BOARD METHOD

RADIATION RESEARCH 66, 401–426 (1976)

The Effect of Multiple Small Doses of X Rays on Skin Reactions in the Mouse and a Basic Interpretation

B. G. DOUGLAS[1] AND J. F. FOWLER

Gray Laboratory of the Cancer Research Campaign, Mount Vernon Hospital, Northwood, Middlesex, HA6 2RN, England

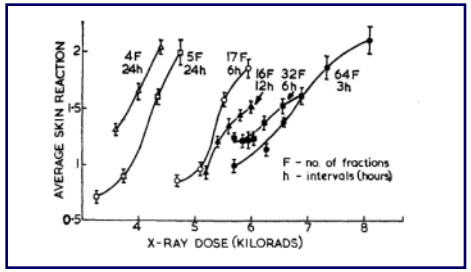
TABLE I

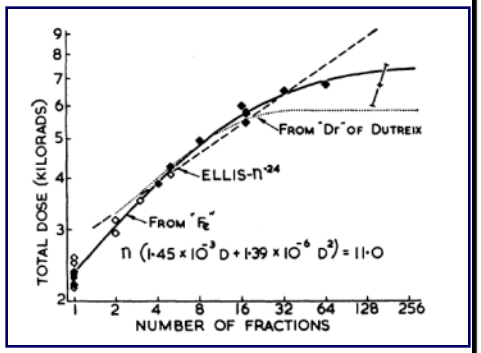
Mouse Foot Skin Reactions[a]

0.0	Normal
0.125	
0.25	Fifty–fifty doubtful if different from normal
0.375	
0.5	Slight hair loss and/or very slight reddening
0.625	
0.75	Definite but slight reddening ± hair loss
0.875	
1.0	Severe reddening, often with distended blood vessels or slight swelling
1.125	
1.25	Severe reddening with white scales and/or severe swelling; red "papery" skin when healing
1.375	
1.5	Moist breakdown of one small area (usually on bottom of foot first) with scaly appearance
1.625	
1.75	Moist desquamation in more than one small area or one slightly larger area (tips of toes stuck together with no other breakdown when healing)
1.875	
2.0	Breakdown of larger area and/or toes stuck together; possibly moist in places
2.125	
2.25	Breakdown of one-third skin area on foot
2.375	
2.5	Breakdown of one-half area of foot (usually first on bottom)
2.625	
2.75	Breakdown of about two-thirds area of foot
2.875	
3.0	Breakdown of most of the skin of foot, possibly with slight moist exudate
3.125	
3.25	Breakdown of entire skin of foot with slight moist exudate
3.375	
3.5	Breakdown of entire skin of foot with severe moist exudate; may be stuck to body fur

[a] It is the *area of skin* involved that is being scored rather than the severity of breakdown in that area. There is a temptation to give a higher score during the healing phase if, for example, half the skin is broken down but there is a nasty scab on it. This should be scored as 2.5 and not as a 3.0 on the basis of the moist exudate.

Douglas & Fowler, continued





APPENDIX C

The quadratic form obtained here for the cell survival curve is consistent with the postulate that cell death results from lethal interaction of two primary lesions placed close together in the cell. From Neary (*20*), the probability that primary lesions will occur in each of two cylindrical targets in one site in a cell is

$$1 - \exp(-mgk^2)[1 - \{1 - \exp(-mk + mgk^2)\}^2].$$

Here k is the probability that one track through the target will produce a primary lesion, g is the probability that a track that traverses one target will pass through the second target in the same site, and m is the mean number of tracks through the mean projected area of a target in the site.

Multiplying by the mean number of sites per cell N yields the mean number of sites per cell that contain lesions in both targets,

$$\lambda = N\{1 - \exp(-mgk^2)[1 - \{1 - \exp(-mk + mgk^2)\}^2]\}.$$

The possibility of cell death from radiation in the range of doses considered is assumed to be present only in cells with sites containing lesions in both targets. It is assumed that correct repair may be prevented by the interaction of the two lesions.

If the probability that both lesions will not be repaired correctly is p, then the probability of survival of a cell with Θ sites containing lesions in both targets is $(1 - p)^\Theta$. It is assumed that the distribution with respect to Θ is Poisson in form.

Summing over the Poisson distribution yields the surviving fraction s:

$$s = \sum_{\Theta=0}^{\infty} \frac{\lambda^\Theta e^{-\lambda}}{\Theta!}(1 - p)^\Theta = e^{-p\lambda}.$$

Substituting for λ,

$$s = \exp(-pN\{1 - \exp(-mgk^2)[1 - \{1 - \exp(-mk + mgk^2)\}^2]\}). \quad (24)$$

If $mk \ll 1$, the above can be approximated by taking the lowest terms in the expansion of the exponentials and

$$s = \exp(-pN\{mgk^2 + m^2k^2[(1 - gk)^2 - g^2k^2/2]\}).$$

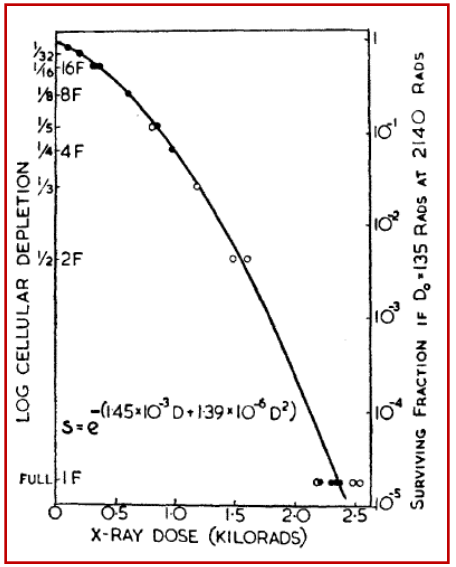
As m is proportional to D, where D is the dose in rads and p, N, g, and k are constants for a given quality of radiation, this can be written as

$$s = \exp[-(\alpha D + \beta D^2)],$$

where α and β are constants. The full equation (24) has the form

$$s = \exp(-\lambda_3[1 - e^{-\lambda_1 D}\{1 - (1 - e^{-(\lambda_2 - \lambda_1)D})^2\}]) \qquad [\text{Eq. (14)}],$$

where λ_2 and λ_1 are proportional to the inactivation constants for one and both members, respectively, of each pair of targets by a single photon, and λ_3 is pN above.



Same end result formula as Lea & Catcheside

Different derivation

Building on the LQ formalism

$$s = \exp[-(\alpha D + \beta D^2)]$$

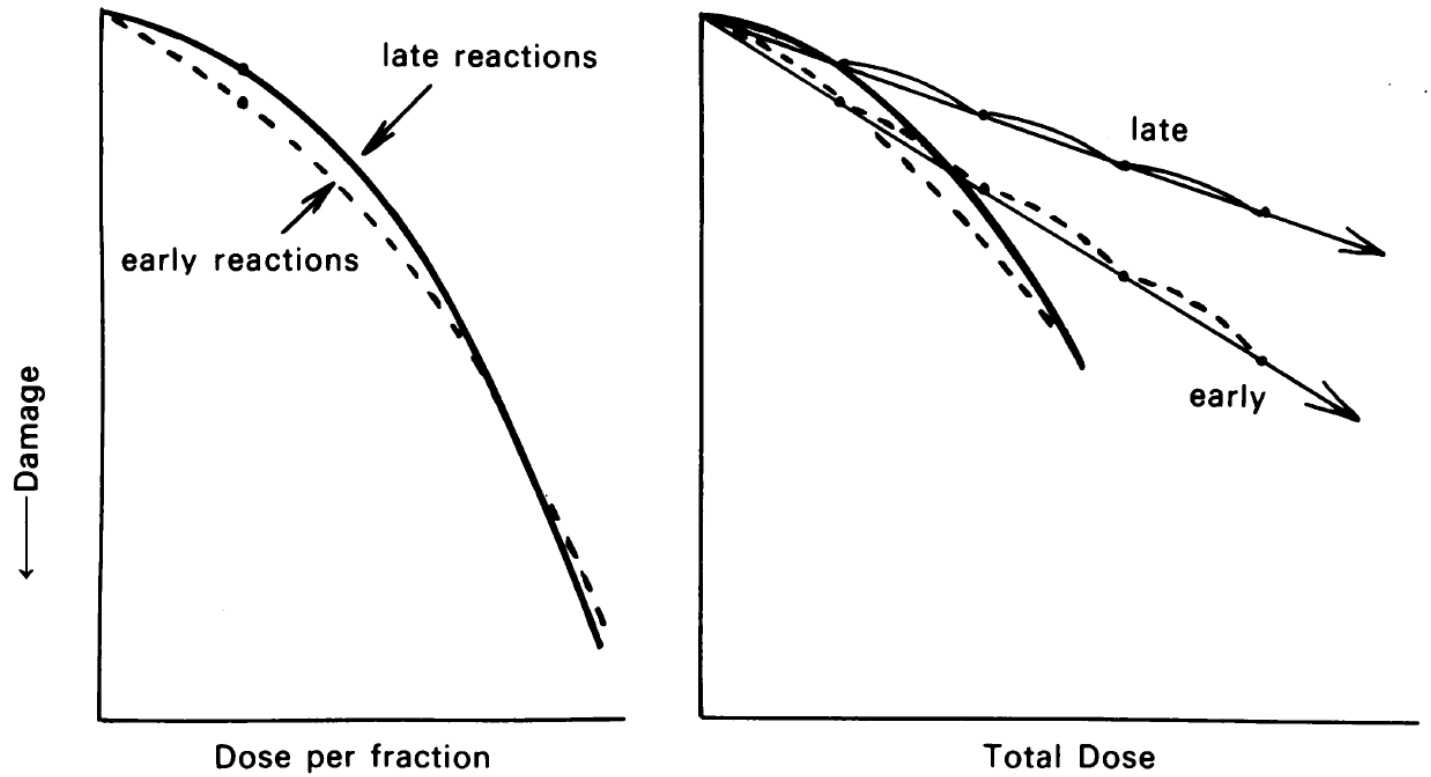


Figure 6 The difference in shape between the dose-response curves for early or late reactions, matched at 200 cGy per fraction. Smaller doses per fraction would require a larger increase of total dose for late than for early reactions.

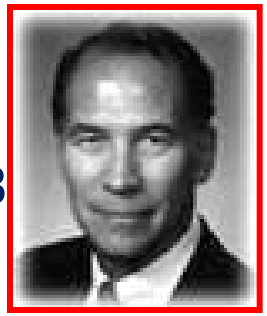
- Average equipment
- Clever low-tech solutions to allow high-tech treatments

Common goal:

- *Kill more cancer, more efficiently*

1st use of term "oligometastases"

Hellman S, Weichselbaum RR. J Clin Oncol. 1995;13(1):8



EDITORIAL

Oligometastases

CANCER TREATMENT is based on an often unstated paradigm of disease pathogenesis. Since 1894, when W.S. Halsted[1,2] clearly elucidated a mechanism of breast cancer spread and used it to design and support the radical mastectomy, surgical and radiotherapeutic approaches to most cancers have been based on this theory. The Halsted theory proposed that cancer spread is orderly, extending in a continuous fashion from the pri-

more about the multistep nature of the development of malignancy.[11-13] Once tumors become invasive, they may gradually acquire the properties necessary for efficient and widespread metastatic spread.[14] Therefore the likelihood, number, and even sites of metastases may reflect the state of tumor development. This suggests that there are tumor states intermediate between purely localized

"Conformal radiotherapy now being investigated for the treatment of primary tumors may find the treatment of oligometastases its most important application…

This technique allows both an increase in the tumor dose and a reduction in normal tissue toxicity by restricting…the radiation to the…tumor while avoiding critical normal tissues…

It requires … precise reproducible … radiation delivery…"

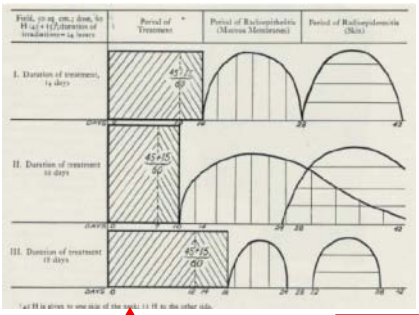
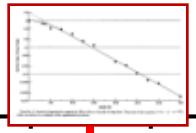
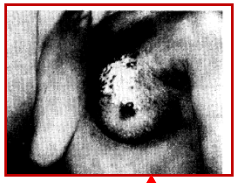
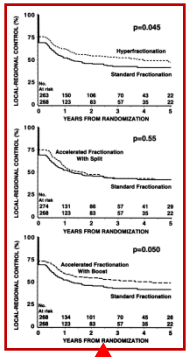
Do "expeditive" RT: and measure dose!

Be careful with normal tissues









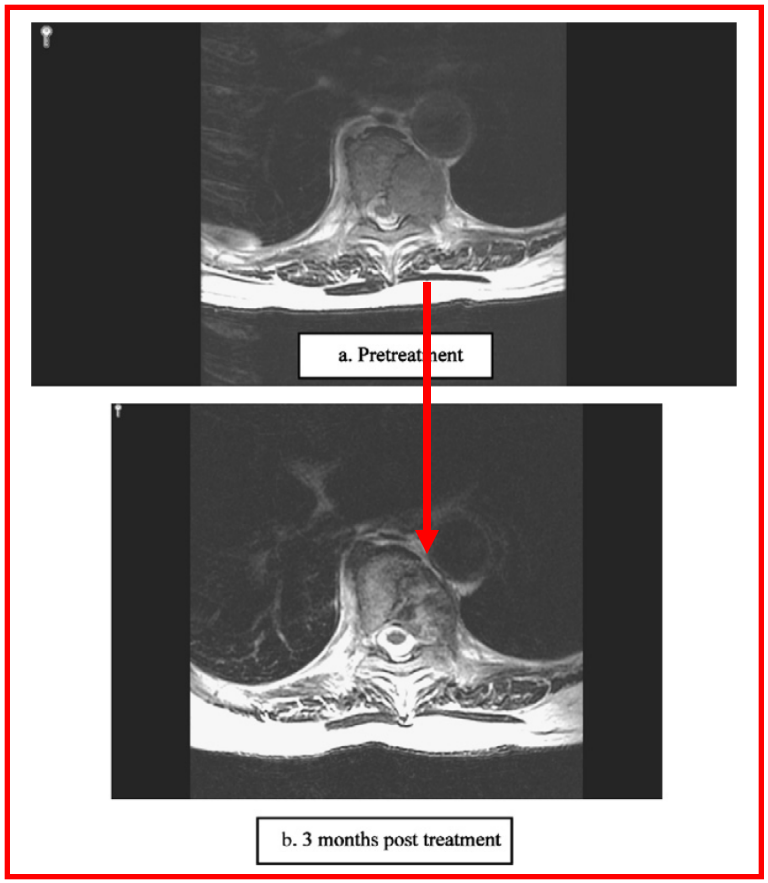
1900 1910 1920 1930 1940 1950 1960 1970 1980 1990 2000 2010 2020

New technology can help us here!

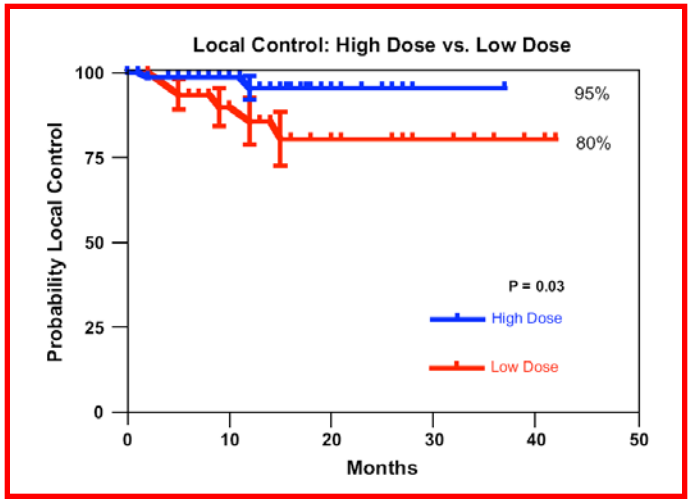
21st century radiobiology

Radiation as potent anti-angiogenic:

Obervations from the MSKCC spinal SBRT experience



Metastatic colorectal ca example



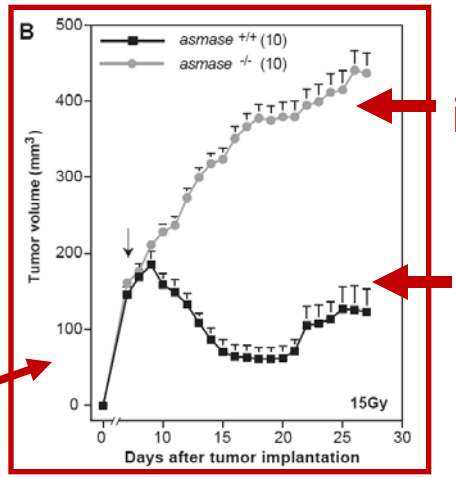
- 93 patients, 103 lesions
  - No spinal cord compression
- Single fraction 18-24 Gy
  - Spinal cord max 12-14 Gy
- Better control at higher dose (24 Gy) than lower (above)

Yamada et al, Int J Rad Oncol Biol Phys 2008; 71(2):484-90

MSKCC argument why SBRT works so well:

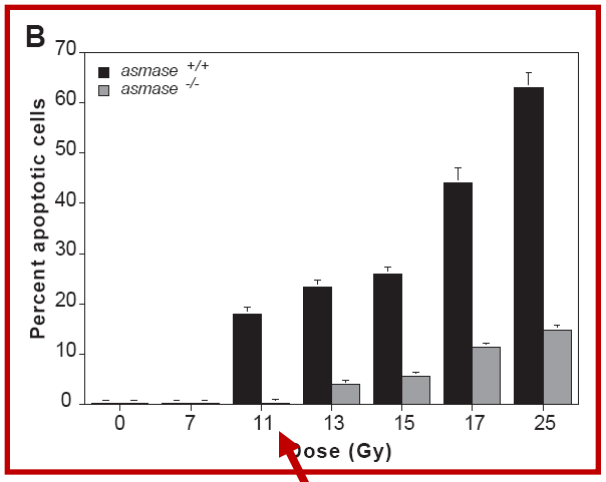
Tumor response to high dose radiotherapy is largely driven by endothelial cell apoptosis

- Fibrosarcoma and melanoma models
- Growth delay after RT influenced by apoptotic capacity
- Dose-dependence of percent apoptosis in endothelial cells



Apoptosis-incompetent

Apoptosis-competent



Threshold?

Garcia-Barros et al, Science, 2003

Sources of guidance for SBRT normal tissue dose constraints

- AAPM TG 101 report
  - Benedict et al, Med Phys, Aug 2010
- Selected RTOG SBRT studies
- QUANTEC papers
  - very limited SBRT, mostly conventional
- Timmerman RD. Sem Rad Onc 18(4): 215-222, 2008
  - Mostly unvalidated but well considered estimates for 1, 3, and 5 fractions

Timeline of Radiotherapy Philosophical Debate about how many treatments should be given: what really happened

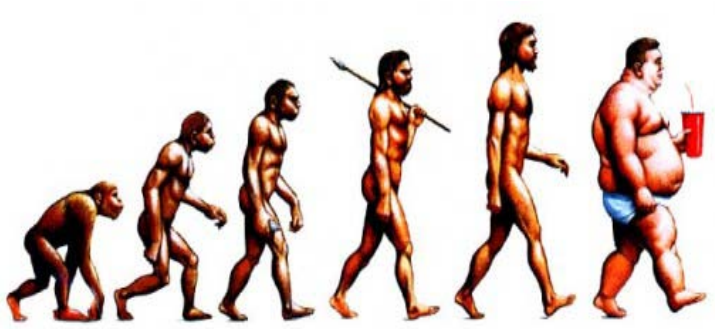
Don't be a fool!

Concurrent chemotherapy explodes everything and makes the nuances of conventional fractionation discussion almost completely disappear

1900 1910 1920 1930 1940 1950 1960 1970 1980 1990 2000 2010 2020

Don't be a Luddite!

Like it or not, this is where radiation oncology has evolved, and there is no end insight to the use of large doses per treatment



Thanks for your attention!
