AbstractID: 11453 Title: Effects of added x-ray beam Cu filtration on image quality and patient dose in digital radiography

Purpose: To quantify effects of added x-ray beam Cu filtration on image quality, skin entrance exposure, and effective dose in digital radiography.

Method and Materials: A GE Definium 8000 DR unit, in AEC mode, was used with a 20 cm thick acrylic phantom to simulate an average adult abdomen. 0.0, 0.1, and 0.2-mm of Cu filtration were added to the x-ray beam. We used 75, 80, 85, 90, 95, 100, and 110kV. Image quality was compared using a contrast-detail phantom (CDRAD). For each beam quality, we exposed the CDRAD phantom on top, below, and between two 10-cm sections of the acrylic phantom, and at four different orientations relative to anode-cathode axis. The results were averaged. Image processing parameters were the ones used clinically for an AP Abdomen exam. The images were analyzed using the CDRAD Analyzer software. Skin-entrance exposures, based on AEC resultant mAs read-out, were measured without backscatter, and effective doses for an average size adult phantom were calculated using the PCXMC software.

Results: At 75-80kV addition of Cu filtration reduced image quality slightly (~1-5%), skin-entrance exposure by 38-52%, and effective dose by 12-21% relative to no additional Cu filtration. At 90-110kV image quality varied little (~0-4%) with added Cu filtration, skin entrance exposure was reduced by 28-47%, and effective dose was reduced by up to 17%. Only at 85 kV image quality was reduced significantly (~13-15%) with added Cu filtration. Skin-entrance exposure was reduced by 35-48%, and effective dose was reduced by 8-17%.

Conclusion: Although already a relatively low dose modality, DR may benefit from the use of additional x-ray beam Cu filtration since, for most x-ray beam qualities, image quality appears to change little, while patient doses are reduced more appreciably compared to using beams with no additional Cu filtration.
